Abstract

We investigate the Japanese personal income distribution in the high income range over the 112 years 1887-1998, and that in the middle income range over the 44 years 1955-98. It is observed that the distribution pattern of the lognormal with power law tail is the universal structure. However the indexes specifying the distribution differ from year to year. One of the index characterizing the distribution is the mean value of the lognormal distribution; the mean income in the middle income range. It is found that this value correlates linearly with the Gross Domestic Product (GDP). To clarify the temporal change of the equality or inequality of the distribution, we analyze Pareto and Gibrat indexes, which characterize the distribution in the high income range and that in the middle income range respectively. It is found for some years that there is no correlation between the high income and the middle income. It is also shown that the mean value of Pareto index equals to 2, and the change of this index is effected by the change of the asset price. From these analysis we derive four constraints that must be satisfied by mathematical models.

1 Introduction

The personal income is a basic ingredient of the economics. Hence, a study of its distribution and an investigation of the mechanism behind it have important meaning in the econophysics [1].

The study of the personal income has long history and many investigations have been done. The starting point is about one hundred years ago when V. Pareto proposed the power law distribution of the personal income [2]. He analyzed the distribution of the personal income for some countries and years, and found that the probability density function $p(x)$ of the personal income x is given by

$$p(x) = Ax^{-(1+\alpha)}.$$

Here A is the normalization constant. This power law behavior is called Pareto law and the exponent α is named Pareto index. This is a classic example of fractal distributions [3]. If Pareto index has small values, the personal income is unevenly distributed.

However, today, it is well known that Pareto law is only applicable to the high income range. It was clarified by R. Gibrat that the distribution takes the form of the lognormal distribution in the middle income range [4]. As is well known the probability density function in this case is given by

$$p(x) = \frac{1}{x\sqrt{2\pi\sigma^2}} \exp \left[-\frac{\log^2(x/x_0)}{2\sigma^2} \right],$$

where x_0 is a mean value, and σ^2 is a variance. Sometimes $\beta = 1/\sqrt{2\sigma^2}$ is called Gibrat index. The large variance means the global distribution of the income. Hence the small β corresponds to the uneven distribution of the personal income.

The lognormal distribution with power law tail for the personal income is rediscovered in the beginning of the 80s. In Ref. [5], the investigation were performed for the USA's personal income data for the fiscal year 1935-36. It was confirmed that the top 1% of income follows Pareto law with $\alpha = 1.36$ and the other takes the form of the lognormal distribution. The explanation of the distribution pattern is performed from a thermodynamical point of view.

From the age of J.J. Rousseau, one of the subject of the social science is the theory of the inequality. In economics, many indexes specifying the unevenness of the income distribution have been developed. Among them, Gini index is well known and used in many aspects of the economics. Although Gini index is useful for the measure of the unevenness in the economics, this index has no attraction from the physical point of view. This is because, as shown in this article, different mechanisms are working in each regions of the high income and the middle income.

Although many investigations of the personal income distribution have been performed, data sets are all old. Hence to reanalyze the income distribution by the recently high quality data is meaningful. In a previous article [6], we analyzed two data sets to gain the personal income distribution of Japan in the year 1998. One is the coarsely tabulated data containing all 6,224,254 workers who filed tax returns. The other is the list for the income-tax of 84,515 workers. In that article we translate income-tax data to the income data and connected these two data sets under some assumptions. From these analysis, for the highest income region, we get the result that the personal income distribution of annual year 1998 in Japan follows Pareto law with $\alpha = 2.06$. However, this analysis is incomplete for the middle income region, because the data set for this region is sparse. Hence, the first purpose of this article is to gain the overall

profile of the personal income distribution of Japan in the year 1998. For this purpose, we add sample survey data for the employment income. These are discussed in section 2.

The second purpose is focused on the change of Pareto index α , the mean value of the lognormal distribution x_0 , and Gibrat index β . Although these indexes have been estimated in many countries and many years, a study of the succeeding changes of these indexes is not well known. Hence the investigations of the temporal change of these indexes have important meaning. In addition, we study the correlation between α and β . This is because, if the change of the distribution of the high income and that of the middle income consists in the same mechanism, the explicit relation between them is expected. Moreover to study the reason of the change of α more detail, we investigate the correlation between α and asset prices, especially the land price index and the Tokyo Stock Price Index (TOPIX). These are discussed in section 3. Section 4 is devoted to the summary and discussion.

2 Lognormal distribution with power law tail

The *income data* contains the person who filed tax return individually. This is a coarsely tabulated data. We analyze this data over the 112 years 1887-1998 in this article. The data is publicly available from the Japanese Tax Administration (JTA) report and the recent record is on the web pages of the JTA [7]. The example for the year 1998 is listed in the second column in Table. The first column of Table is the classification of the income x with the unit of million yen.

The *employment income data* is the sample survey for the salary persons working in the private enterprises, and does not contain the public servants and the persons with daily wages. This data is coarsely tabulated as same as the income data. We analyze this data over the 44 years 1955-98 in this article. This is publicly available from the JTA report and recent record is available on the same web pages for the income data. The distribution is recorded by the unit of thousand people from the year 1964, therefore the data contains the effect of the round-off. The example of this data for the year 1998 is listed in the third column in Table.

The *income-tax data* is only available for the year 1998. This is the list of the 84,515 individuals who paid the income-tax of ten million yen or more in that year. The contained data is reported by the JTA.

To gain the overall profile of the personal income distribution, we connect these data sets. As mentioned in the previous article [6], for the year 1998, we translate the income-tax t to the income x as $t = 0.3x$ in the region above 50 million yen. On the other hand, for the data sets of the income and the employment income, we simply sum up these. From this, we can gain the profile of the personal income distribution over the 44 years. However, we have a point to notice. From the year 1965, all persons with income greater than 20 million yen must file their final declaration to the JTA under the Japanese tax system. Hence individuals with employment income greater than 20 million yen must file their final declaration individually. Thus they are included in the income data. For this reason, we use only the income data for the range greater than 20 million yen. Although there are overlapping persons in the range less than 20 million yen, no detailed information to remove this ambiguity is possible. We call the existence of the overlapping person as the *overlapping effect*. The effect of this will be stated later. The example of above process for the year 1998 is summarized in the fourth column in Table. From these process we have the data for 51,493,254 individuals; about 80% of all workers in Japan.

Table: Japanese personal income distribution in the year 1998.

Classification x -million yen	Number		
	Income	Employment	Total
$x \leq 0.7$	14,496	3,294,000	3,381,848
$0.7 < x \leq 1$	73,352		
$1 < x \leq 1.5$	359,157	4,639,000	5,539,896
$1.5 < x \leq 2$	541,739		
$2 < x \leq 2.5$	565,835	6,783,000	7,933,824
$2.5 < x \leq 3$	584,989		
$3 < x \leq 4$	954,901	8,118,000	9,072,901
$4 < x \leq 5$	687,057	6,587,000	7,274,057
$5 < x \leq 6$	497,438	4,796,000	5,293,438
$6 < x \leq 7$	375,485	3,485,000	3,860,485
$7 < x \leq 8$	288,141	2,428,000	2,716,141
$8 < x \leq 9$	379,716	1,647,000	3,129,716
$9 < x \leq 10$		1,103,000	
$10 < x \leq 12$	229,205	1,995,000	2,439,917
$12 < x \leq 15$	215,712		
$15 < x \leq 20$	190,524	394,000	584,526
$20 < x \leq 25$	140,533	79,000	140,533
$25 < x \leq 30$		98,000	
$30 < x \leq 50$	82,519		82,519
$50 < x$	43,455		43,455
Total	6,224,254	45,446,000	51,493,254

The distribution for the year 1998 is shown in Fig. 1. In this figure, we take the horizontal axis as the logarithm of the income with the unit of million yen, and the vertical axis as the logarithm of the cumulative probability $P(x \leq)$. The cumulative probability is the probability finding the person with the income greater than or equals to x . In the continuous notation it is defined by $P(x \leq) = \int_x^\infty dyp(y)$. In this figure the bold solid line corresponds to the adjusted income-tax data. The open circle emerges form only the income data. The filled circle is the result of the sum of the income data and the employment income data. The dashed line and the thin solid line are the fitting of the linear and the lognormal functions respectively. We recognize from this figure that the top 1% of the distribution follows Pareto law with $\alpha = 2.06$. On the other hand 99% of the distribution follows the lognormal distribution. The mean value of the lognormal distribution x_0 is about 4 million yen, and Gibrat index is $\beta = 2.68$. The change from the lognormal distribution to the power law distribution does not occur smoothly. It is considered that the origin consists in the *overlapping effect* stated before. This is because, if we use only the employment income data for the range less than 20 million yen to maximally remove the overlapping person, the number of person in each classifications in that region decrease. Hence the cumulative probability of each income becomes small. This effect is expressed as the downward movement of the filled circle in Fig. 1. Although the value of x_0 and β changes, the pattern of the lognormal distribution is not modified. This is because the middle income distribution of employment income data follows the lognormal distribution with $x_0 = 4$ million

Figure 1: The cumulative probability of the Japanese personal income in the year 1998.

yen and $\beta = 2.75$.

Although the detailed data for the high income is only possible for the year 1998, the overall profile of the distribution is available from the income data and the employment income data as recognized from Fig. 1. Moreover as seen from Fig. 1, the value of α , the absolute value of the slope of the high income distribution, is available from only the income data, open circles in Fig. 1. Hence the reliable value of indexes specifying the distribution is calculable over the 44 years.

The example of the distribution for some years are shown in Fig. 2 (a) and (b). In these figures the plotted data sets are same for each figures. The solid lines in Fig. 2 (a) are the linear fitting of the data for the high income. We recognize from this figure that less than top 10% of the income is well fitted by Pareto law. However the slope of each lines differs from each other. Hence Pareto index differs from year to year. In Fig. 2 (b), the solid lines are the lognormal fitting. It is confirmed from this figure that greater than 90% of persons follow the lognormal distribution. However the curvature of each lines differs from each other. Thus Gibrat index, the variance of the lognormal distribution, differs from year to year. The movement of the distribution toward the high income consists in the increase of the mean income. Hence this change is characterized by the change of the mean value of the lognormal distribution. If we normalize the income by the inflation or deflation rate, this movement may be deamplified.

Figure 2: The cumulative probability of the Japanese personal income for some years.

However, if this manipulation is applied, the profile of the distribution is not modified.

From the analysis of the data sets over the 44 years 1955-98, we can confirm that the distribution pattern of the personal income is expressed as the lognormal with power law tail. This distribution pattern coincides with the result of Ref. [5]. Though the analysis of Ref. [5] and this article are for different years and different countries, the same distribution pattern is observed. Hence we can expect that the lognormal distribution with power law tail of the personal income is a universal structure. However the indexes specifying the distribution differ from year to year as recognized from Figs. 1 and 2. Thus we study the temporal change of these indexes in next section.

3 The temporal change of the distribution

Firstly we consider the change of x_0 of the lognormal distribution. As same as previous section, we can gain the change of it over the 44 years 1955-98 by the numerical fitting. The result is shown in Fig. 3 (a). In this figure the horizontal axis is the year and the vertical axis is the value of x_0 with the unit of million yen. We recognize from this figure that the personal income rapidly increases from the end of the 60s, and this condition continued until the beginning of the 90s. It is reasonable to assume that the origin of the change of x_0 consists in the growth of the country. To confirm this assumption we consider the correlation between x_0 and the Gross Domestic Product (GDP), and gain Fig. 3 (b). In this figure the horizontal axis is the GDP with the unit of tera yen and the vertical axis is the value of x_0 with the unit of million yen. The solid line in this figure is $x_0 \propto 0.00775G$, where G is the GDP with the unit of tera yen. Hence x_0 and the GDP linearly correlate.

Secondly, we consider the change of α and β over the 44 years. We have Fig. 4 from the numerical fitting of the distribution. In this figure the horizontal axis is the year and the vertical axis is the value of α and β . The open circle and square correspond to α and β respectively. It is recognized from this figure that these indexes correlate with each other around the year 1960 and 1980. However these quantities have no correlation in the beginning of the 70s and after

Figure 3: The temporal change of x_0 (a), and the correlation between x_0 and the GDP (b) over the 44 years 1955-98.

Figure 4: The change of α and β over the 44 years 1955-98.

the year 1985. In the range where α and β change independently, the strongly changing index is α . Especially after the year 1985, β stays almost same value. This means that the variance of the middle income is not changing. From these behaviors of α and β , it is considered that there are some factors causing no correlation between α and β , and mainly effecting to α .

Thirdly to study the origin of the change of α more detail, we consider the correlation between α and the asset price such as the land price and the stock price over the recent 19 years 1980-98. The correlation between the land price index and α is shown in Fig. 5 (a). The land price index is defined as the mean value of the land price of that year, normalized so that the land price as of May 31, 1990 is 100. In this figure the horizontal axis is the land price index and the vertical axis is the value of α . We recognize from this figure that these two indexes linearly anti-correlate. If the land price increases, the value of α becomes small. The correlation between α and the TOPIX is shown in Fig. 5 (b). In this figure the horizontal axis is the TOPIX and the vertical axis is the value of α . Though the correlation is not so strong in comparison with

Figure 5: The correlation between α and the land price index (a) and the TOPIX (b).

Figure 6: The change of α over the 112 years 1887-1998.

the case of the land price index, the anti-correlation is observed. If the TOPIX increases, the value of α becomes small. Hence the change of the asset price is one of the origin of the change of Pareto index.

Lastly, as mentioned previously, α is mainly derived from the income data. Hence the change of α can be analyzed over the 112 years 1887-1998. The data analysis are shown in Fig. 6. In this figure the horizontal axis is the year and the vertical axis is the value of α . The mean value of Pareto index is $\bar{\alpha} = 2$, and α fluctuates around it. Japan has experienced various business conditions except for the socialist economy over the 112 years. Hence it is expected that this behavior of Pareto index is applicable for another countries. However to confirm this conjecture is a future problem. The mean value of Pareto index $\bar{\alpha} = 2$ in this case is worth to compare with the case of the Japanese company size and that of the debts of bankrupt companies [6],[8]. In these cases the distribution follows the power law with $\alpha = 1$; Zipf law.

4 Summary and discussion

In this article we investigated the Japanese personal income distribution in the high income range over the 112 years 1887-1998, and that in the middle income range over the 44 years 1955-98. We confirmed from data analysis that the personal income follows the lognormal distribution with power law tail. This structure have been observed in the analysis for the different years and countries. Hence it is the universal structure that the personal income distribution takes the form of the lognormal with power law tail.

From the analysis of the change of α and β , we confirmed that these quantities should not necessary correlate each other. This means that different mechanisms are working in the distribution of the high income range and that of the middle income range. One of the origin of no correlation is the change of the asset price such as the land price and the stock price. The high income distribution is strongly affected by the asset price.

From the analysis in this article, we propose that the following conditions must be satisfied by mathematical models.

1. The model must express the lognormal distribution with power law tail.
2. There are some factors causing no correlation between α and β , and mainly effecting to α .
3. Pareto index must fluctuate around $\bar{\alpha} = 2$.
4. Gibrat index fluctuates contradictory to the random walk.

The most simple model intended to express the mechanism of the distribution is given by R. Gibrat [4] as the multiplicative stochastic process defined by $x(t+1) = b(t)x(t)$. Here $x(t)$ is the income at the time t and $b(t)$ is the ideally independently distributed stochastic variables with positive values. Hence if this process is iteratively used, we have $x(t+1) = b(t) \cdot b(t-1) \cdots x(0)$. Thus the logarithm of this derives $\log x(t+1) = \log b(t) + \log b(t-1) + \cdots + \log x(0)$. Hence $\log x(t+1)$ follows the normal distribution by the central limit theorem. Therefore $x(t+1)$ takes the form of the lognormal distribution. However this process derives the monotonically increasing variance. Moreover the power law tail can not be explained by this process only, and the simple multiplicative stochastic process can not satisfy above conditions. In present, there are some models deriving the power law tail [9]. Though these models does not intend to explain the personal income distribution, to investigate the applicability of these models to the personal income is an interesting problem.
